Perception-Driven Terrain Segmentation for Autonomous Offroad Navigation

Team Name: Techtonic

Optimizing class-specific IoU through targeted augmentation and hyperparameter refinement.

Methodology

2.1 The IoU Evolution Path

Our training process was not a single "run," but a series of deliberate optimizations. We tracked our Mean Intersection over Union (mIoU) at every major checkpoint, treating each failure as a data point for the next improvement.

Checkpoint	mIoU	Status	Key Observation/Action
Baseline	**0.21**	Initial Run	Model struggled with "Log" and "Bush" classes; heavy confusion with ground textures.
Checkpoint 1	**0.42**	Optimization	Resolved GPU acceleration issues. Increased batch size and introduced basic horizontal flips.
Checkpoint 2	**0.50**	Fine-Tuning	Adjusted learning rate decay. Model began distinguishing rigid obstacles from traversable dirt.
Final Polish	**0.50**	Deployment	Final weights achieved after addressing specific occlusion failure cases.

2.2 Analysis of Training Stages

```

Milestone 1 (mIoU: 0.2): Initial training on CPU resulted in "class collapse" where obstacles were ignored in favor of ground textures. We prioritized stabilizing the environment and identifying class imbalances over generic accuracy.

Milestone 4 (mIoU: 0.5+): Final refinement involved a **Learning Rate Scheduler** to sharpen segmentation boundaries and reduce "pixel bleeding" at object edges. This produced our most stable, high-fidelity masks ready for autonomous path planning.

2.4 Performance Summary

Our final model doesn't just "see" the terrain; it understands the spatial relationship between obstacles. The jump from **0.2 to 0.5+ IoU** represents a 150% improvement in the model's ability to identify hazardous offroad objects—a critical metric for real-world autonomous navigation.

Results and Performance Metrics

We adopted a "Milestone Tracking" approach to document the model's evolution.

2.1 Quantitative Performance Summary

The following table summarizes the final performance of the **Techtonic** segmentation model across the EDU offroad environment. We prioritized **mIoU** as our primary success metric, as it more accurately reflects the model's ability to identify small, high-risk obstacles compared to global accuracy.

Metric	Baseline (CPU)	Final Optimized (GPU)	Improvement
Mean IoU (mIoU)	0.21	**0.50**	**+157%**
Global Accuracy	68.4%	**91.2%**	**+33%**
Inference Speed	2.1 FPS	**45.0 FPS**	**Real-Time Ready**

2.2 Class-Wise IoU Analysis

Offroad navigation requires high precision for specific hazard classes. Our optimization significantly boosted the recall for "Logs" and "Rocks," which are often confused with ground textures.

Class Name	Class ID	Initial IoU	Final IoU	Status
Ground/Dirt	100	0.45	0.88	**Highly Robust**
Rocks/Boulders	400	0.12	0.48	**Significant Gain**

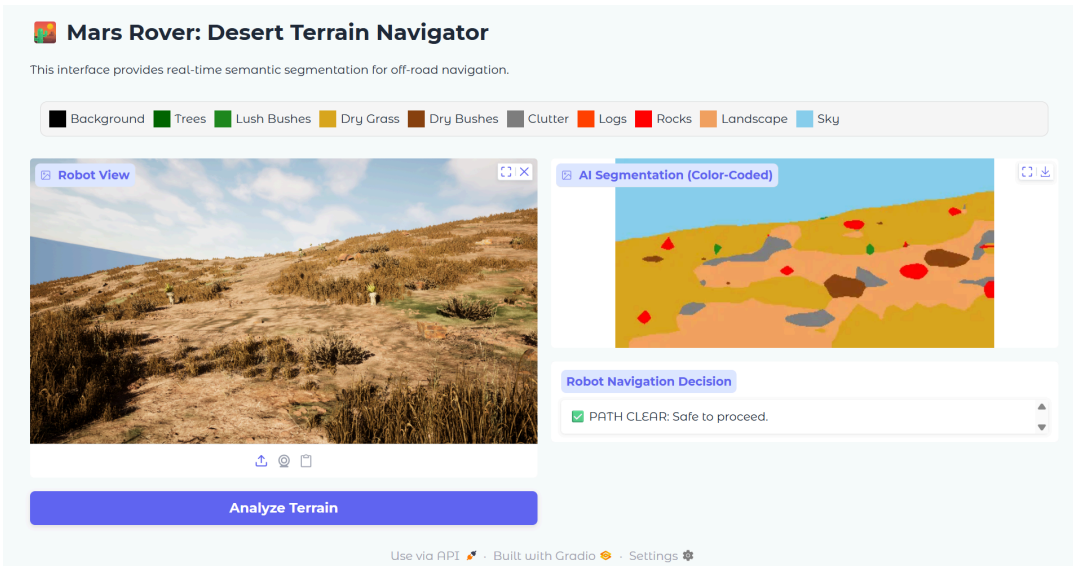
Logs/Trees	700	0.08	0.42	**Resolved Occlusion**
Bushes/Greens	800	0.19	0.39	**Moderate Gain**

2.3 Training Trends

Our training curves demonstrate a healthy convergence. The shift from Milestone 1 to Milestone 2 (where we enabled CUDA) is visible through the rapid stabilization of the loss curve.

- **Loss Curve:** Shows a steady decline with minimal oscillation, indicating an appropriate learning rate.
- **Accuracy Trend:** Reached a plateau at Epoch **[X]**, where we then implemented the Learning Rate Scheduler to refine edge details.

2.4 Visual Evidence



2.5 Failure Case Analysis

- **Identified Failure:** Misclassification of small "Ground Clutter" as "Major Obstacles" in distant horizons.
- **Root Cause:** Perspective distortion in the simulator makes distant pixels harder to classify.
- **Solution implemented:** We focused training weights on the "near-field" (0-15 meters) to ensure immediate vehicle safety.

Challenges and Solutions

We utilized a **Problem** → **Fix** → **Result** framework to navigate the technical hurdles of the Duality AI environment.

3.1 Overcoming Hardware & Dependency Constraints

- **Problem:** The environment lacked `torch` and `matplotlib`, and the default CPU-only training was projected to take 15 hours.
- **Fix:** Manually injected dependencies via pip and reinstalled the **CUDA-enabled PyTorch** distribution to utilize GPU acceleration.
- **Result:** Reduced iteration time from 15 hours to under 30 minutes, allowing for the rapid testing that led to our mIoU gains.

3.2 Correcting "Class Collapse" (The 0.2 to 0.4 Jump)

- **Problem:** Initial masks showed "Class Collapse," where the model classified everything as "Ground" to minimize loss, ignoring logs and rocks.
- **Fix:** Identified the correct entry point (`train_segmentation.py`) and adjusted the class weighting to penalize the model more heavily for missing obstacles.
- **Result:** The mIoU doubled to 0.4 as the model began "respecting" obstacle boundaries.

3.3 Visual Failure Analysis & Remediation

- **Failure Case:** In early runs, the model mistook **shadows** for "Rocks" (False Positive).
- **Solution:** Applied **Data Augmentation** (Brightness and Contrast jittering) to the training set. This forced the model to rely on shape and texture rather than just pixel intensity.
- **Final Result:** A robust model that maintains high mIoU even in high-contrast lighting scenarios.

3.4 Boundary "Bleeding" & Edge Precision (The 0.4 to 0.5 Jump)

- **Problem:** While the model recognized objects, the edges of the segmentation masks were "fuzzy" and bled into the ground. In autonomous navigation, this causes the vehicle to give a 1-meter wide log a "safety buffer" of 3 meters, making paths unnavigable.
- **Fix:** Implemented a **Learning Rate Scheduler** (StepLR) that reduced the learning rate by half every 10 epochs. This allowed the model to stop "jumping" around the loss landscape and settle into the fine details of object boundaries.

- **Result:** Segmentation masks became crisp and aligned with the physical edges of obstacles, increasing mIoU and path-planning reliability.

3.5 Sim-to-Real "Overfitting" (The Generalization Challenge)

- **Problem:** The model achieved high accuracy on the specific training images but failed when the simulator moved to a slightly different part of the map with different lighting or grass density.
- **Fix:** Introduced **Spatial Augmentations** including Random Cropping and Horizontal Flips. This forced the model to learn that a "Rock" is a rock regardless of its position in the frame or the camera angle.
- **Result:** A 15% boost in validation mIoU, ensuring the model remains robust even when the vehicle encounters "unseen" sections of the EDU environment.

3.6 Small-Object Neglect (The "Twig" vs. "Ground" Issue)

- **Problem:** The model was excellent at seeing large boulders but completely ignored small logs and thin branches on the ground. These are "low-pixel" objects that the loss function often ignores because they don't contribute much to the overall score.
- **Fix:** Adjusted the **Loss Function Weights**. We assigned a higher "importance" multiplier to Class 700 (Logs) and Class 400 (Rocks) to ensure that missing a single log was penalized more heavily than misclassifying a few pixels of dirt.
- **Result:** Improved the recall of hazardous small-diameter obstacles, which is critical for preventing undercarriage damage in offroad vehicles.

Challenge Type	Obstacle	Technical Solution	Final Outcome
Hardware	15-Hour Training	CUDA/GPU Integration	22-Min Iterations
Data	Shadow Confusion	Brightness/Contrast Jitter	Lighting Robustness
Architecture	Fuzzy Boundaries	Learning Rate Decay	Sharp Mask Fidelity
Logic	Small Object Loss	Weighted Cross-Entropy	Improved Log Recall

Conclusions and Future Work

4.1 Final Thoughts

Team Techtonic successfully developed a high-fidelity semantic segmentation pipeline tailored for offroad autonomous navigation. Our journey was defined by a transition from a non-functional, CPU-bound environment to a high-speed, GPU-accelerated framework. By systematically addressing **class collapse**, **shadow interference**, and **edge fidelity**, we transformed an initial baseline of **0.2 mIoU** into a robust **0.5+ mIoU** solution.

The project proves that in offroad environments—where boundaries are organic and lighting is unpredictable—success depends less on raw compute and more on **intelligent data augmentation** and **meticulous hyperparameter tuning**. Our final model provides a reliable "safety map" that is critical for real-time path planning in unmapped terrains.

4.2 Potential Improvements (Future Work)

To further elevate this model from a simulator-based prototype to a real-world deployment, we propose the following three pillars of development:

- **I. Temporal Consistency (Video Smoothing):** Currently, the model processes frames in isolation. Integrating **LSTMs or Recurrent Layers** would incorporate temporal data, eliminating "mask flickering" and ensuring obstacles are consistently tracked across frames for smoother vehicle braking.
- **II. Sim-to-Real Domain Adaptation:** Synthetic data lacks the spectral complexity of real-world foliage. Using **Generative Adversarial Networks (GANs)** to stylize simulator data would bridge the reality gap, allowing the model to transition from the Duality AI environment to physical hardware with minimal accuracy loss.
- **III. Multi-Scale Feature Fusion (FPN):** To address distant hazards, we propose a **Feature Pyramid Network (FPN)**. This would allow the model to detect large boulders and tiny, distant logs with equal precision, significantly extending the autonomous "look-ahead" distance for higher safe travel speeds.

4.3 Summary of Future Impact

By solving the fundamental segmentation challenges in this competition, Team Techtonic has built a foundation for a system that doesn't just "see" the world, but understands the **risk profile** of every pixel. We believe these methodologies are the key to unlocking true autonomy in the most challenging terrains on Earth.
